Fire and Climate History in the Western Americas From Tree Rings

THOMAS W. SWETNAM
Laboratory of Tree-Ring Research, The University of Arizona, Tucson, Arizona, USA; tsweetnam@ltrr.arizona.edu

The usefulness of tree rings in historical climatology derives from their high temporal resolution, exact dating, and sensitivity to precipitation and temperature variables. Another key strength of tree-ring climate proxies is that they can be massively replicated across broad-scale networks encompassing regions, continents, and hemispheres. In addition to influencing the growth of trees, climate variations affect ecological processes, and these processes are also recorded within tree rings. One of the most climatically responsive ecological processes is the occurrence and extent of wildfires. The record of past forest fires is often beautifully preserved within tree-ring sequences as “fire scars” on the lower boles of trees (Fig. 1). By extensively sampling fire-scarred trees in numerous locations, dendroecologists are now assembling broad-scale fire-scar chronology networks (Fig. 2) that are approaching the extent and replication of tree-ring width networks that dendroclimatologists have been assembling since the 1960s.

In combination with calibrated precipitation and temperature reconstructions from tree rings, fire-scar networks help improve our understanding of ecologically-effective climatic change. These records can assist in identifying important changes in regional to global climate patterns, and they can be useful in developing models for forecasting fire hazards in advance of fire seasons. In this brief note I review examples of findings from fire-scar networks in the western Americas.

Regionaly Synchronized Fire Events

One of the strongest indications that fire-scar chronologies can reflect climatic variations is the occurrence of synchronized fire-scar events in widely scattered locations, from forest stands to regional scales (Fig. 3A). These regional fire events typically coincided with drought years (Fig. 3B). Similar patterns of fire event synchrony and drought are observed in the 20th century. For example, 1988 and 1989 were severe drought years in the western United States, and enormous areas burned during these years (e.g. the 1988 fires in Yellowstone National Park, and many large fires in the Great Basin and Southwest in 1989). Extensive fires occurred at the global-scale in the El Niño years of 1982-83 and 1997-98 in tropical forests of Indonesia, central Mexico, and the Amazon Basin.

A combination of modern and paleo time series of fire occurrence and weather indicates that high and low fire extent years were often associated with extreme phases of the ENSO (La Niña and El Niño). These patterns were not simply ENSO-related droughts causing high fire occurrence, or wet periods
causing low fire occurrence, but also included inter-seasonal and inter-annual lagging patterns. For example, a common finding in the Rocky Mountains of Colorado, Arizona and New Mexico, in the Sierra Nevada of California, northern Mexico, and Patagonia and in Argentina was that the most extensive fire years tended to be dry years following 2 or 3 wet years (Fig. 3C). Moreover, the smallest fire years tended to be wet years that followed a dry year. These lagging relations occurred primarily in semi-arid woodlands and forests, and were most likely due to the importance of growth and accumulation of fine fuels (i.e. grasses and tree needles). Wet conditions in prior years were necessary for sufficient accumulation of fine fuels to carry surface fires in these open forests with widely spaced trees.

Combined with improved inter-seasonal climate forecasting based on ENSO conditions, these lagging patterns hold promise for developing useful fire hazard forecasting models. Fire managers could use these forecasts to position additional fire-fighting resources in advance of bad fire seasons, or to plan for conducting more “prescribed burns” during less hazardous seasons. These kinds of forecasting tools are currently in development and testing in the western and southern United States, where ENSO teleconnections are particularly important to seasonal precipitation amounts. Additional studies of paleofire records will be useful to identify the changing strength and consistency of ENSO-fire teleconnections, both spatially and temporally.

Inter-Regional Comparisons of Fire and Climate

An exciting research opportunity in paleofire climatology is the assembly and comparison of regional fire histories along the PEP-1 transect (Pole-to-Equator-to-Pole) in the western Americans (Fig. 2). We know that ENSO has important effects on seasonal precipitation and temperature along this transect, and these teleconnections are inverse between some regions. For example, rainfall amounts in the Pacific Northwest and northern Rocky Mountains of North America are usually opposite in response to El Niño and La Niña events relative to the southwestern and southeastern United States (e.g. El Niño events are dry in the NW and wet in the SW and SE). Recent studies have shown that paleofire records tend to follow these patterns: extensive fire events in Oregon tended to correspond with the El Niño phase of ENSO (Heyerdahl et al. in press), while extensive fire events in Arizona and New Mexico tended to correspond with La Niña events (Swetnam and Betancourt 1998). Because ENSO, the Pacific Decadal Oscillation (PDO) and other broad-scale ocean-atmosphere patterns modulate precipitation and temperature variations at regional to inter-hemispheric scales, we should expect that fire activity would be synchronized at similar scales. Indeed, in an inter-hemispheric comparison of fire-scar chronologies (Kitzberger et al. 2001), we found that fire activity in the southwestern United States was synchronous with fire activity in Patagonia Argentina from circa AD 1700 to 1900. Precipitation regimes in these two regions are affected in similar ways by ENSO. Not only were the two regional fire chronologies coherent within the ENSO frequency band (i.e. 2 to 7 years), we noted a similar decadal-scale secular change in the two fire-scar time series from circa 1780-1830. These are low fire frequency decades, and they coincided with an exceptionally cold period in both hemispheres (e.g. see the Mann et al. (1999) temperature reconstruction for the northern hemisphere). Moreover, this period had a markedly reduced frequency and amplitude of ENSO events, as indicated in tree-ring width, coral and ice core isotopic reconstructions (Kitzberger et al. 2001). In another study, using a fire-scar network from giant seqouia groves in the Sierra Nevada of California, we found that decadal fluctuations in temperatures were correlated with fire frequencies over the past 2,000 years (Swetnam 1993).

New Fire-Scar Chronology Networks and Multi-Proxy Fire Histories

These encouraging results indicate that there is high potential to use fire-scar networks to evaluate interannual to decadal-scale climate variability. We are at an early stage in the development of regional paleofire networks, and there is a need for new collections in unsampled regions where interesting climatic teleconnections are expected. For example, networks of crossdated fire-scar chronologies are needed from British Columbia and southeastern Alaska, the Great Basin, and from additional regions in Chile and Argentina. Development of fire-scar chronology networks in the subtropics and tropics of Mexico, Brazil, Peru, and other countries will be challenging because annual tree rings are difficult to discern in many of the tree species in these regions. Nevertheless, an effective strategy might focus on sampling in high mountain areas, and regions with seasonal-
ly variable rainfall patterns and fire regimes.

Assembly of many, well-dated fire-scar chronologies from multiple locations is a key to identifying fire-climate patterns. This will require sustained efforts and coordinated data sharing among investigators and laboratories. Educational exchange and financial support is needed to assist in developing new laboratories and trained paleofire dendrochronologists. There should be opportunities to do this by coordinating efforts with other tree-ring initiatives, such as the PEP-I, Inter-American-Institute tree-line dendrochronology project (see Luckman and Boninsegna, PAGES News 9(3):17-19, Dec. 2001).

Another promising area of investigation is the linking of the tree-ring paleofire records with sedimentary charcoal records. When sampled from the same watersheds and drainage basins, or when the sedimentary records have high temporal resolution (e.g. varves, or fine interval sampling and \(^{210}\text{Pb}\) dating), there may be opportunities to crossdate fire events between tree-ring and sediment-charcoal time series. This kind of multi-proxy approach could be very useful in distinguishing local versus regional fire events. Combined with pollen time series from the same areas, coordinated tree-ring/sedimentary charcoal studies could provide new insights on the multiple scales of climatic change, fire regime and vegetative responses spanning years to millennia, and local areas to regions.

Paleofire climatology has great potential to improve our understanding of the effects of past climate variations – especially those variations relevant to ecosystem change. Other indirect climate proxies, such as lake levels and glacier fluctuations are commonly cited as corroborating evidence in support of climate reconstructions from tree rings, corals, and ice cores. It is now clear that paleofire time series are of similar and increasing utility as an independent measure of ecologically-effective climate change.
