Extending Isotope in Precipitation Data Beyond Direct Measurements: The Perspective From Glacier Ice-Core Measurements in Switzerland

Ulrich Schotterer¹ and Willibald Stichler²

For paleoclimatic applications of stable isotope records two premises have to be fulfilled, namely, (1) that the isotope composition of the proxy material can be related to the water cycle of the past, and (2) that the relevant hydroclimatic parameters contributing to the record can be evaluated. Ice cores clearly play a central role within the goal of ISO-MAP, because they potentially provide one of the most direct archives of paleoprecipitation, yet basic monitoring and process studies in situ are required to ensure that the transfer functions between the isotopic composition of the precipitation that is preserved and the conditions at the time of its formation are clearly elucidated.

Isotopes have been measured regularly in monthly composites of precipitation in Switzerland since 1970. The official Swiss network for isotopes in the hydrological cycle, operated by the Federal Office for Water and Geology, became operational in 1992. The network data cover the principal hydrometeorological regions of Switzerland at different altitudes, and therefore afford a unique opportunity to extend data records back in time via linking with high-resolution measurements from ice cores (or other archives).

Particularly well-resolved ice-core records have been obtained from the cold Fiescherhorn Plateau, situated in the Berner Oberland at an elevation of 3950 m (see Frontpage and upper panel, Fig. 1), which was drilled in both 1987 and 2000. The glacier is characterized by a notably high accumulation rate (1-2 m of water equivalent per year), potentially providing extremely fine temporal resolution. Isotopic determinations ($\delta^{18}$O, $\delta^2$H, $\delta^3$H) were accompanied by measurement of a suite of relevant environmental tracers at close intervals, constituting up to 35 samples per year. As shown in Figure 1 (middle panel), systematic annual cycles of variation in $\delta^{18}$O are clearly apparent for the entire Fiescherhorn record, anchored on some discrete time markers, suggesting that the series is continuous and complete. Given this unprecedented degree of resolution and the quality of accompanying meteorological information, this data set should be ideally suited for rigorous evaluation of the hydrometeorological information archived in this alpine glacier. Yet this task is not straightforward, since the challenge of defin-
Holocene Variability in the Indian Ocean Monsoon: A Stalagmite-Based, High-Resolution Oxygen Isotope Record from Southern Oman

DOMINIK FLEITMANN1, STEPHEN J. BURNS2, MANFRED MUDELSEE3, ULRICH NEFF4, JAN KRAMERS4, AUGUSTO MANGINI4 AND ALBERT MATTER4

The Indian Ocean monsoon is one of the major weather systems on Earth, affecting the economies, agriculture and fisheries of one of the most densely populated areas of the world. To date, analyses of how and why the monsoon varies through time have mainly been restricted to studies of meteorological records, which extend back perhaps 150 yr, or to investigations of lacustrine and marine sediments, which have a low time-resolution (typically greater than 100 years) and large age uncertainties. However, one sensitive monitor of monsoon variation having considerably finer temporal resolution is the oxygen isotope composition of stalagmites, such as those from Qunf Cave (17°10’ N, 54°18’ E; 650 m a.s.l.) in

Fig. 1: a Modern summer circulation pattern over Southern Oman. The red star shows the location of Qunf Cave. The black dashed line shows the position of the temperature inversion and the red dashed line the location of the ITCZ. b Schematic figure of summer circulation pattern at around 7 kyr BP.

Fig. 2: Comparison of net annual accumulation at Fiescherhorn and precipitation amount at Grimsel. The lack of correspondence, consistent with the weak isotopic correlation evident in Fig. 1, underscores the need for critical evaluation of alpine ice core records.
