Introduction

Large drought variability has occurred over the past 2000 years. To study the climate relationships that influenced drought, a data assimilation approach is employed. Better understanding past drought variability may help us prepare for potential changes over the coming century.

The Last Millennium Reanalysis (LMR) project is a data assimilation approach which uses information from proxy records and climate models to reconstruct past climate.

Prior:
- Output from CCSM4 last millennium simulation.
- Proxies:
  - PAGES2k x²¹
  - Trees compiled by P. Breitenmoser².
  - Additional NCDC proxies.

Method:
- The Kalman filter updates the prior climate state to better match proxies. The proxies inform temporal variability and model covariances help fill in spatial information.

1. Data Assimilation

2. LMR compares well with existing data sets

Temperature and drought in LMR match well with existing data sets. An advantage of LMR: A unified approach to reconstruct a variety of climate variables simultaneously.

3. U.S. drought vs. ENSO

Drought in the southwest U.S. covaries with La Nina sea surface temperatures and a cold Pacific Decadal Oscillation, as seen in mode 1 of a maximum covariance analysis. Possible connections with the Atlantic Multidecadal Oscillation are not as clear.

4. Climate patterns of the driest and wettest years

The driest years in the southwest U.S. have a clear La Nina pattern and a blocking high in the north Pacific. The opposite is true for the wettest years.

5. Other things affect drought too

For the southwest U.S., El Nino years can be dry and La Nina years can be wet, defying expectations.

6. Possible effects of volcanic eruptions

Volcanic eruptions have a clear impact on temperature, but might have affected past droughts as well. The response may depend on the location of the eruption².
